

Unsung hero of the electrochemical cell: the wave front traveling near c

Conal Boyce

Century College, century.edu

Abstract:

We present the electrochemical cell in a schematic that emphasizes distance traveled by an electromagnetic wave doing laps around the cell's notional perimeter at near light speed. What could be the impetus for focusing on such an "exotic" aspect of the cell? A desire to close the gap between 20 minutes and 78 million years, where the former is the observed duration of a representative procedure (for the electrolysis of, say, 0.15g Cu), and the latter is the same procedure's calculated duration based on the (generic) electrochemical cell presentation found in our textbooks. Per long-standing convention, where the student might reasonably expect a pedagogical MODEL she is presented instead with a picture whose labels speak of a self-evident REALITY, wherein "electrons flow" from anode to cathode via a battery/lead system that serves as the "conduit" while ions migrate in solution "to complete the circuit." If we take to heart that familiar picture, assigning rates 0.0002 m/s for electron drift and 0.000004 m/s for ion migration, the time required to react 0.15g of copper appears to be many millions of years; whereas, if we re-do the picture as a proper electric circuit, the calculated duration falls easily within the ballpark of the observed 20 minutes. The term 'electron flow' seems to speak of something tangible and edifying, but it should be accompanied by a warning label: Hard-Science Factoid. As it turns out, charges wafted by an ephemeral electromagnetic wave near c are what we need instead to make the numbers work.

Keywords: electron flow, electrochemistry, conventional current, photon, drift velocity, charge transport, science education

Introduction

In Part One, I present a scheme for (re-)introducing electricity (not to be confused with *electrons* creeping at a snail's pace), as the driving force of electrochemistry. For a preview, please refer to Figure 1. In Part Two, I try to impose some structure on the no-man's-land where electrochemistry and physics overlap. There too the presentation relies heavily on graphics; see Figures 2-4.

Next, I document the use of the term 'electron flow' (and symbol ' $e^- \rightarrow$ ') in a variety of texts. The examples that I've culled from general chemistry texts comprise Part Three; the examples from specialized electrochemistry texts comprise the fourth and final part of the article. (This longish documentation step is important for substantiating my claim that 'electron flow' is the ubiquitous term/concept around which a conventional representation is built, and for showing, in part, why 'electron flow' is, nonetheless, a factoid.)

In Concluding Remarks, I sketch out the underlying philosophy that motivated me to devote time to "the 'electro' in electrochemistry," a topic that might seem obvious and/or frivolous at first glance.

Part One: Photons surfing the wave front: The unsung heroes of electrochemistry

My first order of business will be to persuade you that the schematic in Figure 1 *is* in fact a reasonable representation of an electrochemical cell. Its appearance, relative to the usual textbook representation, is admittedly exotic. To achieve some perspective, think of the doughnut/coffee mug equivalence that the science journalist uses as an introduction to topological thinking. (See inset in northwest quadrant, courtesy of arizona.edu.) My departure from the standard representation of an electrochemical cell involves some stretching and shrinking, yes, but on balance the distortions I introduce are comparable to (or somewhat milder than) those required for a doughnut to become a mug. Next question: But *why* did I apply these transformations? My immediate goal was to present a picture where the gap between the electrodes, and the lengths of the three leads, are all roughly to scale, so that one might quantify the electrical circuit's perimeter and associated attributes.

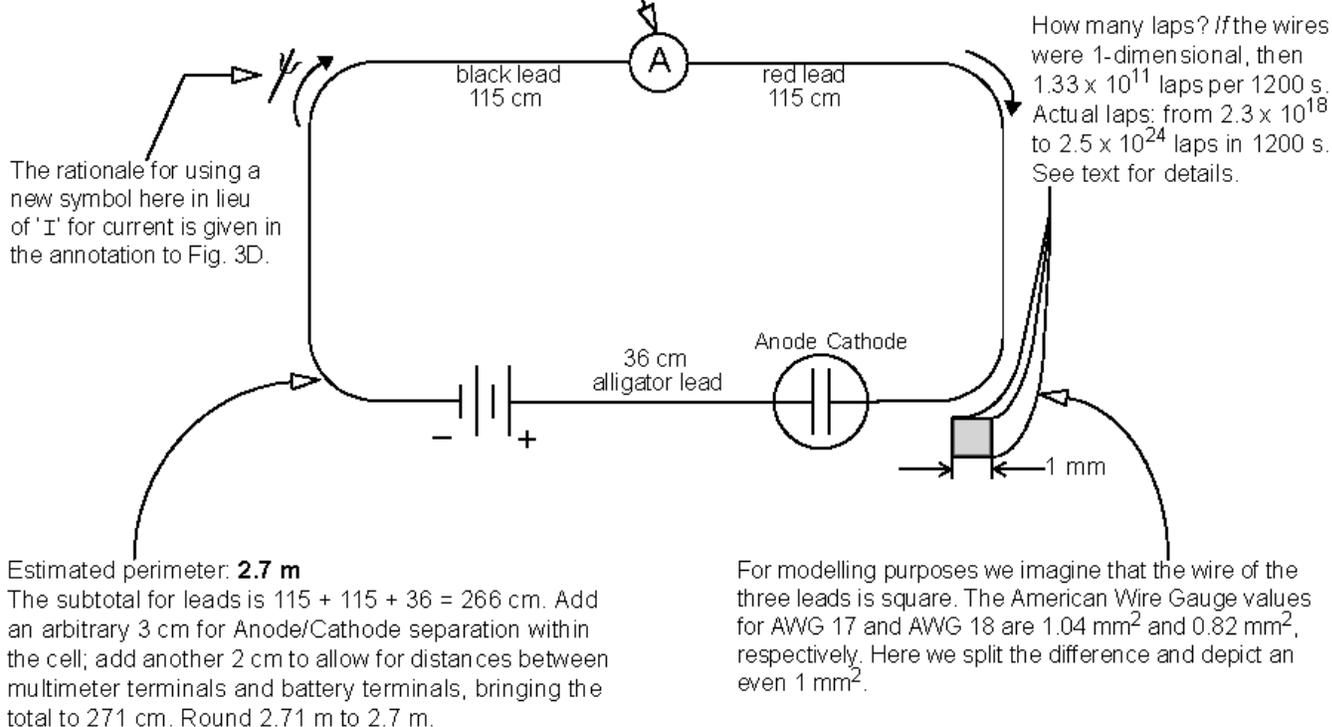

The diagram below is my proposed **generic** scheme for representing a wide variety of electrochemical cells. For the purpose of rounding out the picture and bringing it to life, I also borrow (arbitrarily) these **specific** data from a published procedure, one whose goal happens to be the determination of Avogadro's number by electrolysis, using two copper electrodes submerged in CuSO_4 : $I = 0.400 \text{ A}$, $t = 1200 \text{ s}$, $\Delta m = 0.1575 \text{ g}$. Source: Seiglie [1], who presents the well-known Estimated N_A Formula in this form:

$$N_A = \frac{Q \cdot M}{e \cdot Z \cdot \Delta m}$$

where $Q = I \cdot t$
 M is Gram Atomic Mass of the metal
 e is the elementary charge, $1.602 \times 10^{-19} \text{ C/e}^-$
 Z is the charge state
 Δm is the mass of metal gained/lost via electrolysis.

With the help of a multimeter in Ammeter mode we observe that approximately 3×10^{21} charges are transported during each 1200-second run of a certain N_A estimation experiment.

How fast does electricity travel in copper? At $2/3 c$. For our purpose, though, let's keep it simple and say: At c . (The difference has negligible impact on an order-of-magnitude calculation.) Borrowing some data from [1], we take the quotient of $480 \text{ C} \div 1.602 \times 10^{-19} \text{ C/e}^-$, and round it to 3×10^{21} charges. (Why 'charges'? The symbol ' e^- ' is overloaded, as discussed in Part Two of this article. Here it refers to charge, e , because — stated in terms of the Estimated N_A Formula above — it is the quotient Q/e that we are taking.) So, 3×10^{21} is the approximate number of charges transported during the 1200 s run of the procedure, a quantity that is readily accommodated by the lap capacity (or bandwidth) of the circuit, which must fall between 2.3×10^{18} and 2.5×10^{24} laps (per 1200 s). The point of all this: Our scheme reconciles a 1200s procedure with the observed gain/loss of 0.1575g Cu whereas the conventional representation implies a process that would take millions of years to finish. See text for further details.

Figure 1: Why does the electrolysis of 0.15g Cu require only 1200 seconds, not 72 million years?
 The short answer, distilled from the graphic: Because charge transport occurs near c .

(Not that I would encourage the pursuit of such detailed parallels, but *if* one wished to form a direct analogy, one could say the conventional representation of an electrochemical cell, with its focus on a round beaker, corresponds to the doughnut in the Figure 1 inset, while my scheme corresponds to the coffee mug, whose looped handle, last vestige of the doughnut, corresponds to our circular diode symbol, last vestige of the beaker.)

To prevent the circuit diagram in Figure 1 from being too abstract and generic, I marry it to specific data from the electrolysis procedure in an article by Seiglie [1], a synopsis of which can be seen in the northeast quadrant. Near the bottom of Figure 1, I derive the number 3×10^{21} indirectly from Seiglie's article, and identify it as the number of charges transported during a 1200-second run of his procedure. Given the crucial role played by that number in my overall formulation, I compute it here a second way, as a check on myself, so to speak: Divide Seiglie's Δm , which is 0.1575 g, by 63.5, the Gram Atomic Mass of copper, and multiply that quotient by N_A , then double the result to convert from bivalent ions to individual charges. This distinctly different path leads us around to the same number, 3×10^{21} charges.

Now, in those 1200 seconds, how far can we go? Assuming 3×10^8 m/s for an order-of-magnitude calculation (rather than $2/3 c$ in copper) the distance is 3.6×10^{11} m. Divide that figure by an estimated perimeter of 2.7 m (assuming for the moment a 1-dimensional circuit, meaning wire of negligible thickness) to obtain the corresponding number of laps feasible in 1200 seconds: 1.33×10^{11} laps. Next, factor in the copper wire's thickness. Copper's density is 8.5×10^{19} atoms/mm³, so its cross-sectional density is approximately 1.9×10^{13} atoms/mm² (obtained by taking the cube root of 8.5×10^{19} , which is 4330085, and squaring it; cf. [18, 34]). Referring to the 1 mm² wire depicted in the diagram, the number of channels available for "parallel processing" of charge transport must fall between 4330085, if we count only the "skin" of the wire, and 1.9×10^{13} channels, if we treat the wire as a solid. Accordingly, the number of charges transportable must fall between 2.3×10^{18} and 2.5×10^{24} . (Calculation details: To account for all four sides of the square wire, $4 * 4330085 = 17320340$. Multiplying the latter times 1.33×10^{11} laps per channel gives us 2.3×10^{18} . Multiplying 1.9×10^{13} channels above by 1.33×10^{11} gives us 2.5×10^{24} laps after cancellation of channels.) This much lap capacity (or bandwidth) easily accommodates the actual quantity of charge transport observed in this instance, which is **3.0×10^{21} charges.**

When all is said and done, the above annotation to Figure 1 involves only plain logic and simple arithmetic (albeit with some large figures). Why, then, should one be impressed by or excited about the resultant numbers? Because there is a striking disparity between the Figure 1 results and their textbook counterparts. Not that one can go directly from one to the other in a single step, but if we were to take certain conventional electrochemical rates to their logical conclusion, we would be looking at 78 million years for Seiglie's electrolysis procedure to run, instead of 1200 seconds. (Based on experiences that you and I have had with countless similar procedures, one judges the 1200-second duration given in Seiglie's article as entirely plausible. As for my half-facetious "78 million years," please refer to Part Three for calculation details.)

Part Two: Glossary

With Figure 1, I have already presented the gist of the article; accordingly, one may skip from here to Concluding Remarks. But for the reader who might be interested in knowing what drove me to that unusual view of the terrain, this section contains a set of definitions, the details of which recount the story, indirectly. The process entailed both critical reassessment of and much zigzagging between certain physics and electrochemistry definitions. When first working out the definitions, these are the questions that were occupying me: Why do textbooks show 'electron flow' in connection with electrochemistry, and nothing ever about electric current (i.e., electricity) itself? What *is* 'electron flow'? How can we best depict (actual) electricity in the electrolysis context? The questions are deceptively simple in appearance, and my search for their answers took me longer than I care to admit. Along the way, those questions sometimes became entangled with the definitions themselves; saying it another way, some of these will not be pure definitions, rather definitions with a slight "agenda" baked into them, and no apology.

ELECTRON DRIFT and DRIFT VELOCITY: In metal, there is a sea of delocalized electrons, each of which traces out its own Brownian Motion-like zigzags. In the presence of an electric field, this "drunkard's walk" has superimposed upon it a secondary movement called *electron drift*. A measurement of the latter phenomenon, which proceeds at a glacial rate, is called its *drift velocity* [1, 3]. Note the counterpoint of phenomena that are rapid (but unvectorred) with phenomena that are exceedingly slow (though vectored), *neither* of which has yet the slightest resemblance to *electricity*, which is where we are headed ultimately in this glossary.

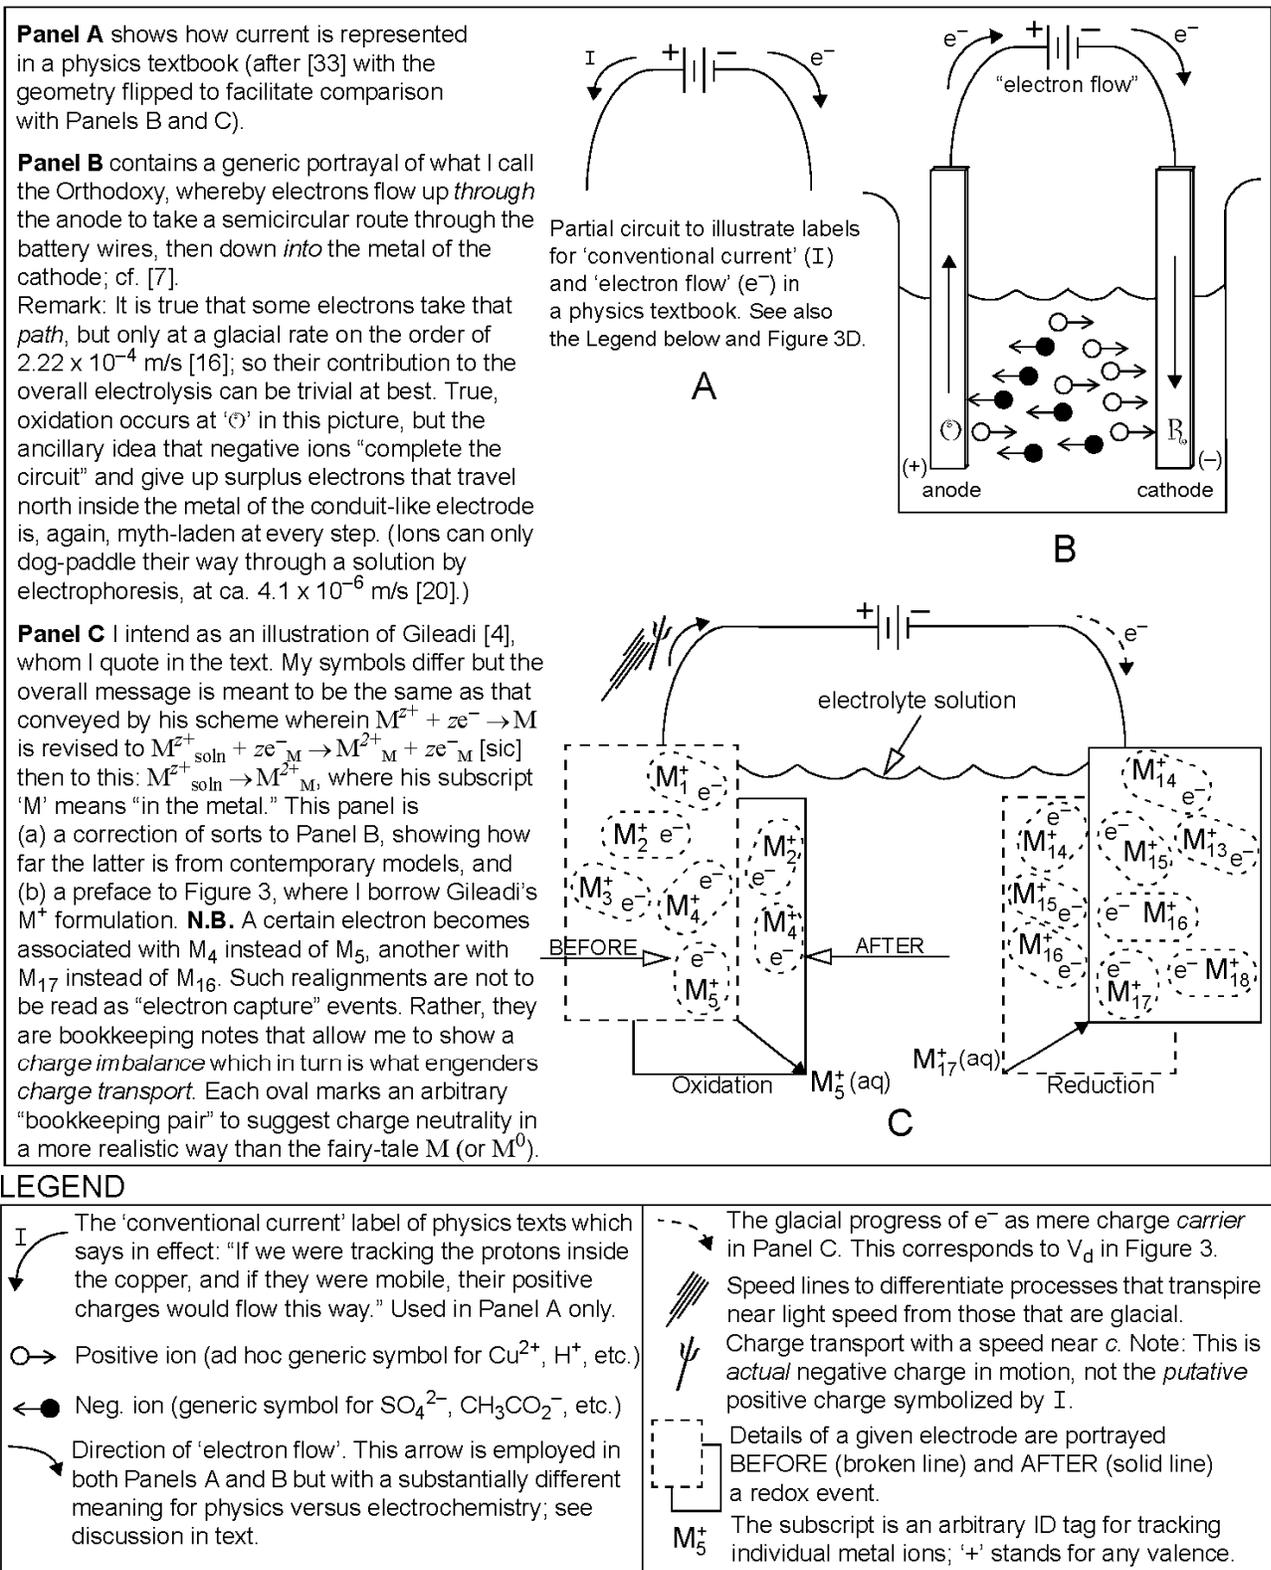

Figure 2: The Physics Legacy; the Orthodoxy; and Redox à la Gileadi

CURRENT: *charge transport per unit of time*. This may be represented algebraically as $I = \Delta Q/\Delta t$ or physically in terms of amperes, which is to say as coulombs per second: $A = C/s$. For more about ‘I’ please skip ahead to Figure 4. There are several oddities of linguistic usage to beware: While the word ‘current’ alone means charge transport per unit of time, the words ‘electric current’ together are usually employed as a synonym for ‘electricity’ — meaning charge transport *en masse*, let’s say, not per unit of time; see definition below. As for ‘conventional current,’ see separate entry, next.

CONVENTIONAL CURRENT: The ‘conventional current’ label of physics says in effect: “If ours was an antimatter galaxy, positrons would drift, and the positive charges would fly, through (anti-copper) wires in the direction of this arrow.” (The arrow itself goes arbitrarily clockwise or counterclockwise; cf. Figure 2A.)

THE TERM ‘ELECTRON FLOW’ IN PHYSICS: In freshman physics, the term ‘electron flow’ plays the following **minor role**: It is kept on hand to provide a counterpart to CONVENTIONAL CURRENT ($I\leftarrow$) so that actual electric activity likewise has a name, and a matching retrograde symbol, that’s all. Meanwhile, conventional current and electron flow are regarded as “exactly equivalent” [33]. This formalism has unintended adverse consequences: Just when a discussion should move forward to distinguish ‘electron flow’ from ‘electron drift,’ and to observe the speed contrast that is mentioned in our definition of ELECTRON DRIFT above, it takes a left turn into the argument for treating clockwise and counterclockwise as topologically equivalent, thus directing the students’ attention to a mathematical formalism — when it should be focused instead on learning about electricity.

THE TERM ‘ELECTRON FLOW’ IN ELECTROCHEMISTRY: Meanwhile, the same term plays a **major role** in electrochemistry (with ‘conventional current’ typically absent from the picture until it is mentioned for completeness’ sake in certain of the fourth-year specialized electrochemistry texts). But what does ‘electron flow’ *mean* in electrochemistry, absent its counterpart as *raison d’être*? Feeling no need to define the term, the author of an electrochemistry chapter invariably presents it as the name of a self-evident phenomenon, as if to say, “Obviously, electrons flow through wires; we all know *that* already.” (But an objective observer, far from accepting ‘electron flow’ as axiomatic, might well wonder if it is not a factoid. It is.)

ION FLOW: In the standard representation, while electrons are said to flow through the several metallic components of an electrochemical cell, ions migrating in the aqueous region are said to “complete the circuit.” This may sound plausible at first glance, but the only way a circuit can actually be completed is by electricity. I.e., an electric field, too, must be present in the solution, advancing at near light speed in the same direction as the dog-paddling ions.

THE ORTHODOXY: To the tradition built on ‘electron flow’ and ‘ion flow,’ I assign the name ‘the Orthodoxy,’ for easy reference. (The Orthodoxy is characterized by an idea of the electrochemical cell that involves a notional conduit, the two ends of which are submersed in a tub or beaker wherein “the circuit is completed”; see Figure 2B. Note that there exists no such *model* in the literature, only a *notion*, underscored by innumerable pictures. Here I use ‘notion’ in a special sense. The phrase ‘racial tension’ today occupies a conceptual plane of its own. Physical anthropologists and biologists may heatedly debate whether there is such a thing as race, but in the meantime, the term ‘racial tension’ lives on in perpetuity, in a mental space that is immune to the workaday modeling, hypotheses and (presumptive) facts of scientific inquiry. Like ‘brain-fever’ in 19th century literature or ‘racial tension’ today, ‘electron flow’ is (only) a notion. Not that any of these seems to result from an intentional end run around the scientific process, but such terms appear on the scene — somehow — as *faits accomplis*.)

ELECTRICITY aka ELECTRIC CURRENT: the *transfer of charge* near c ; the propagation of electromagnetic waves in metal, e.g., in copper wire. Note that neither of my defining phrases contains the word ‘electron.’ In the literature, meanwhile, we are inundated by the notion, expressed explicitly in some physics contexts and implicitly throughout electrochemistry, that Electricity Equals Electrons-in-Motion. That definition is blatantly false. When electrons move by dint of their ‘drift velocity,’ that is merely a condition that *correlates* with electric current. If we aspire to represent the role of electrons in electricity, there can be no shortcuts: we must tell the *whole* story, as portrayed in Figure 3.

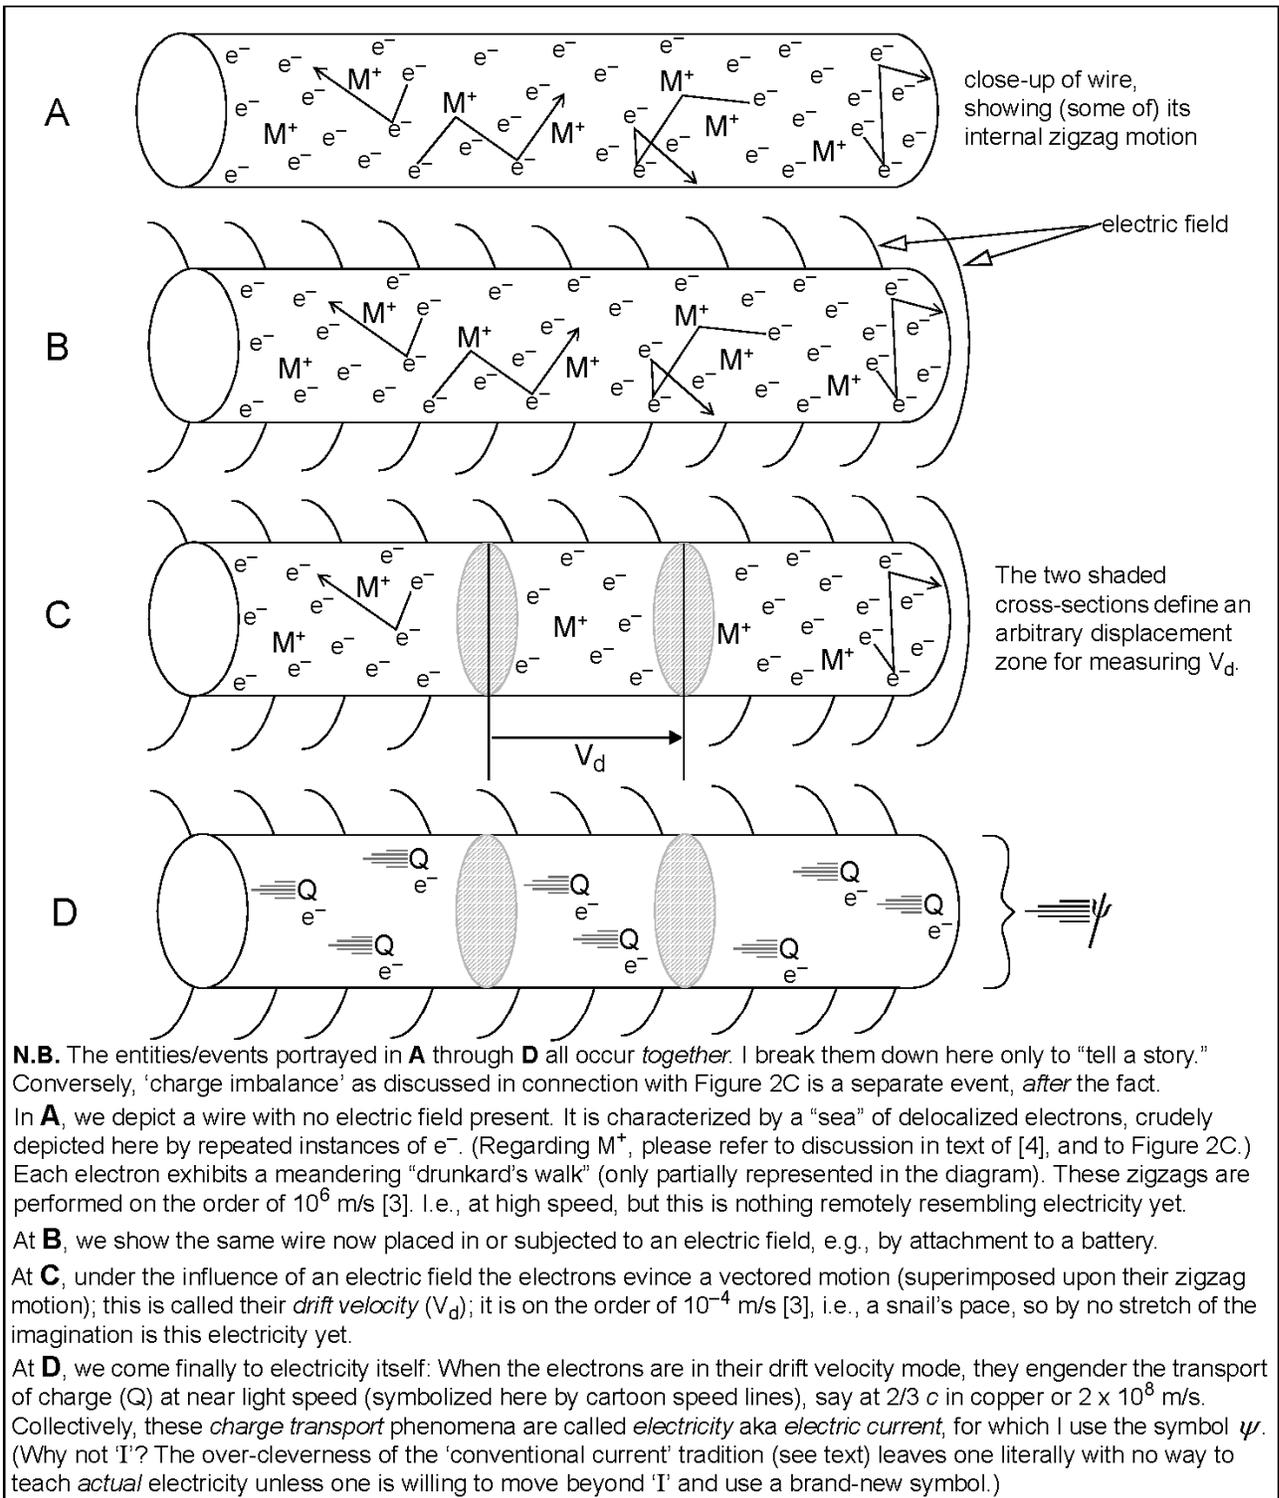

Figure 3: Electricity defined as a phenomenon with four distinct (though simultaneous) layers

(Regarding M^+ in Figure 3 please refer to Figure 2C which is my illustration of the following redox formulation by Gileadi: Metal deposition “is often represented [as $M^+ + e^- \rightarrow M$] [but] metals do not consist of neutral atoms. They consist of positively charged metal ions ‘immersed’ in a sea of delocalized electrons. [The] electrons are in the metal, both in the initial and in the final states. The only species that is moved from one phase to the other is the metal cation.” [4] If we used conventional notation, Gileadi’s version of redox would come down to these two statements: Oxidation is $M^+(s) \rightarrow M^+(aq)$. Reduction is $M^+(aq) \rightarrow M^+(s)$. Expressed thus, the idea will seem strange. With the schematic in Figure 2C, I endeavor to illustrate Gileadi’s thinking. At the same time, 2C provides a layer of infrastructure that I reuse for my own purpose in Figure 3.)

Further notes on the physics legacy: In Figure 4, I use a flow chart to represent the tangled genealogy of certain coulomb-related terms. In the commentary panel, I indicate which parts make sense, which parts are subtle, and which parts are just barnacle-like appendages to the underlying logic. Similar to the case of conventional current, the family of pseudo-definitions surrounding ‘ $C = A \bullet s$ ’ numbs the mind with puzzles that leave over just enough *psychological* energy to worry about Getting the Right Answer. I stress ‘psychological’ because the puzzles are never intellectually challenging, only messy — a test of the student’s tolerance for cipher-manipulation, not her intelligence.

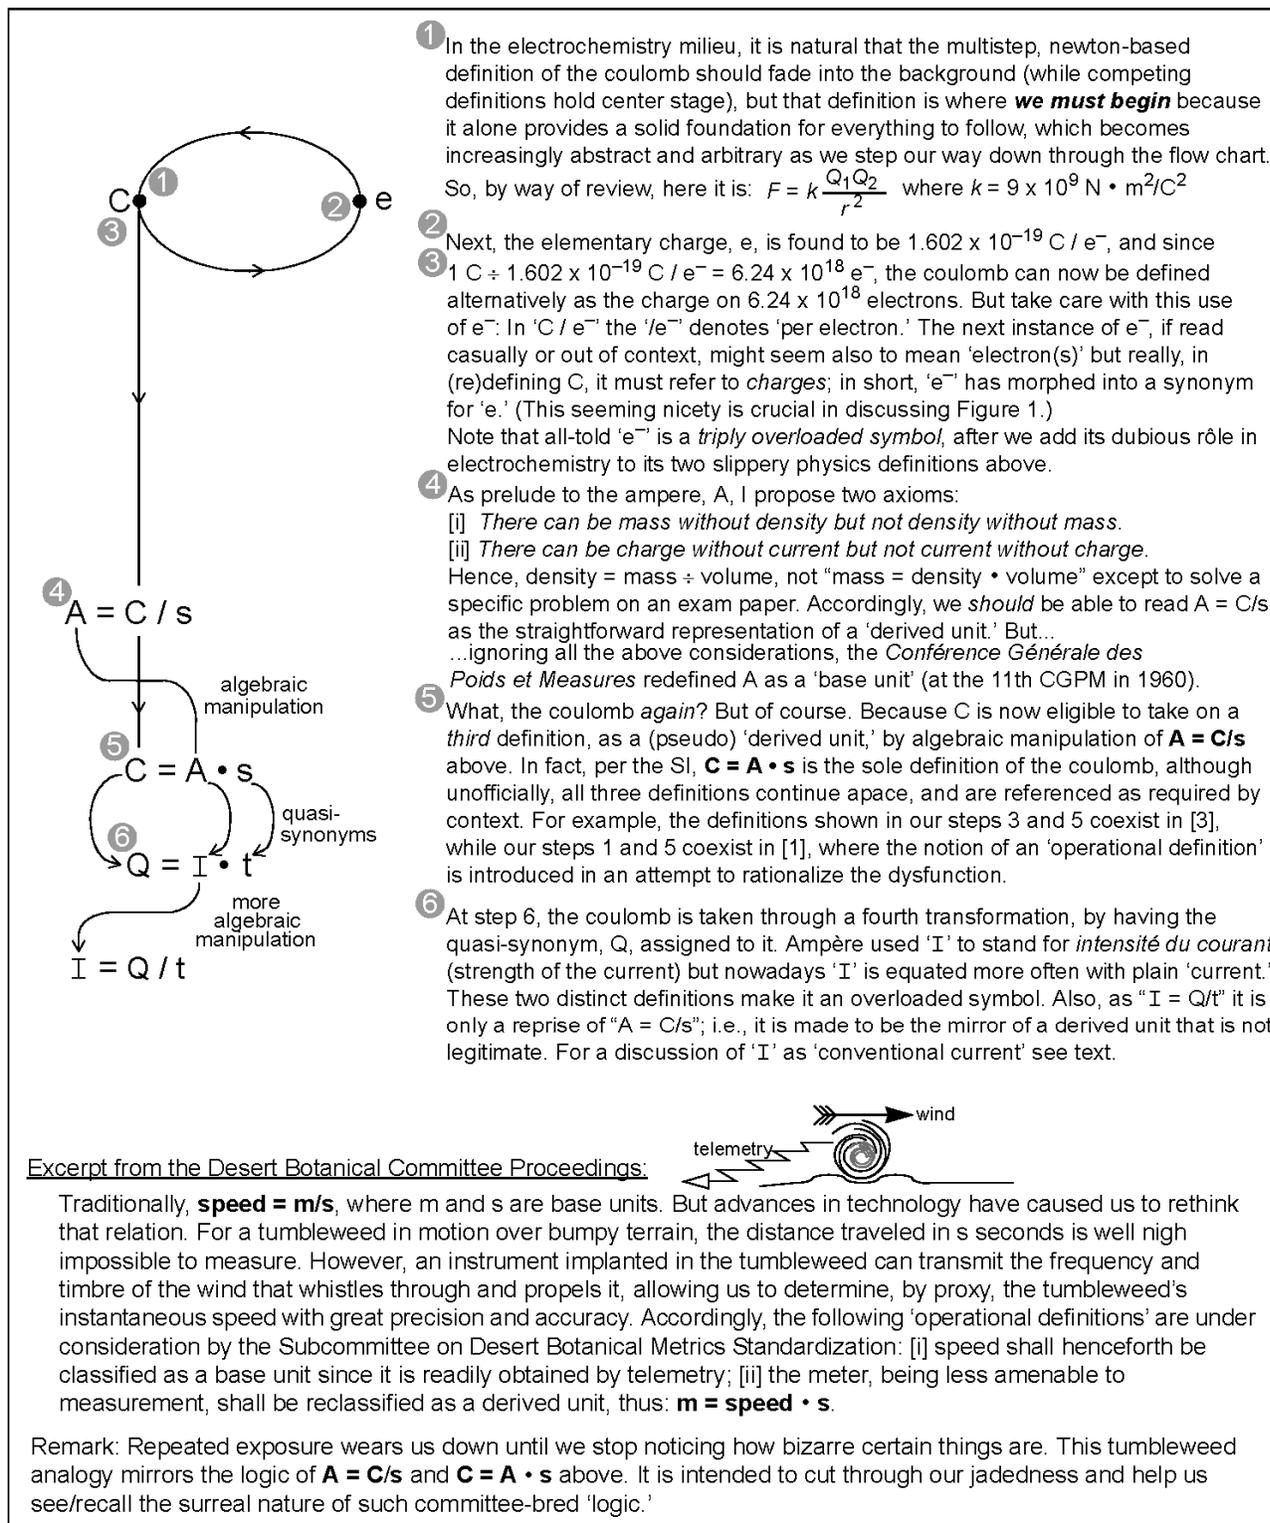

Figure 4: The many faces of C (the coulomb) and the pedigree of I (current)

For relief from the unpleasantness of Figure 4, let's spend a moment looking at a positive counterexample: Leonard Susskind's reinvention of temperature as a derived quantity, which implicitly turns the kelvin from an SI base unit into a derived unit. In a 2013 lecture, Susskind said: "Temperature is the rate of change of energy with respect to entropy" [5]. And on the whiteboard he wrote $dE = T \cdot dS$, thus turning on its head the entropy formula that you and I learned by rote ($\Delta S = q/T$), mindful to express our answers in units J/K. Similarly, five years earlier in *The Black Hole War* Susskind had written: *Temperature is the increase in the energy of a system when you add one bit of entropy* [6]. This was a great stride forward in resolving the riddle of black hole information loss, he felt. Regardless of one's stance on that thorny (and still *unresolved*) issue, one has to admire his boldness with the units: Without waiting half a century to see if a faceless committee might eventually agree with him, Susskind has summarily replaced 'base unit' K by a 'defined unit' of the same name, and perhaps even transformed the 'defined unit' S into a 'base unit,' trading in nearly two centuries of $\Delta S = q/T$ for his own $T = q/\Delta S$ epiphany. Here we have the flip side of the unthinking algebraic manipulation that is thrown into relief by Figure 4. The point of this interlude about Susskind is that if one proposes the revision of a base/derived relation *in good faith*, it can be a legitimate exercise, even a highly valuable one (granted most of us lack the clout to go public with such a maneuver as Susskind's).

Sources: In the various definitions above, much of the wording is my own, but I draw also on several physics texts [1-3] to provide some of the technical underpinning, along with [4], already cited. For the definitions at steps 1, 3 and 5 in Figure 4, I rely on [3] and [33].

Part Three: Where and how 'electron flow' appears in the instructional literature

The instructional literature I divide into two categories: (a) the electrochemistry chapters in general chemistry textbooks and physical chemistry textbooks; (b) specialized electrochemistry texts that straddle the fourth-year and graduate school levels. In these pages (Part Three) I document the widespread use of the term 'electron flow' and label ' $e^- \rightarrow$ ' in literature category (a). In Part Four, I do a survey of (b), the specialized electrochemistry texts, to see if/how they move beyond the notion of 'electron flow' as presented to freshmen.

"I am challenging the conventional model of the electrochemical cell," is what one would like to say here. But we are precluded by the circumstance from doing so. We find ourselves dealing with a fixed, canonical NOTION of something; this is substantially different from having an abstract

MODEL set before us. Thus, having no MODEL to critique, we are inclined at first to try rationalizing the NOTION by asking: Could it be that the textbook author *writes* ‘electron flow’ (and/or ‘ $e^- \rightarrow$ ’) but *thinks* ‘electric current,’ by virtue of a simplifying assumption or math-style formalism? No, there is no support for that idea either. Eventually we are driven to conclude that *literal electrons* are the object of discussion (and this is troubling, because ‘electron flow’ is a factoid, occupying a conceptual limbo, in-between electromagnetic waves that soar and [actual] electrons that creep).

The following excerpts are taken from a random sampling of chemistry and physical chemistry texts. Here we find that the notion of ‘electrons flowing’ was endorsed by Linus Pauling [7], no less, and has been canonized in books that span more than half a century. Not shown: Each quoted passage is reinforced by a graphic (immediately or a few pages hence) that features the label ‘ $e^- \rightarrow$ ’ and/or ‘electron flow.’ All italics and bolding are added. Cumulatively, the various italicized terms demonstrate the prevalence of the Orthodoxy over the period 1947-2011 (at the very least). The terms that I’ve bolded are ones that seem to hint at a broader view — but usually these disappoint us by failing to definitively challenge the Orthodoxy.

A. When the circuit is closed *electrons flow* as through a tube [...] The battery acts as an *electron pump* [...] An electron is *pumped into* the cathode [...] The **charge** [...] is conducted across the liquid *by the motion of the ions*. [7]

B. A battery causes **charge** to move through a wire [...] **Current** is defined as the **charge** passing a point per unit of time [...] *electrons flow* [...] *through the wire*. [8]

C. When the reaction between MnO_4^- and Fe^{2+} occurs in solution, the electrons are transferred directly when the reactants collide. Thus no useful work is obtained [...] thus requiring the *electron transfer* to occur *through a wire*. The **current** produced in the wire by the *electron flow* can then be directed [...] to produce useful work [...] obtain the total *coulombs of charge passed* into the Cu^{2+} solution [...] 0.187 mole of *electrons flowed* into the Cu^{2+} solution. [9]

D. [*E*] *lectrons flow* from one metal electrode to another *through an external circuit*, while *ions flow* [through the solution]. [10]

E. In an electrochemical cell [reactions can occur] only if *electrons flow* through an *outside* conductor [...] *Electrons move* from the negative electrode (anode) to the positive electrode (cathode) *through the external wire*. The electrical circuit is *completed* in the solution *by the movement of ions*. [11]

F. [The anode] *supplies electrons to the external circuit*. [12]

G. [The] term ‘electrode’ [...] is also used to mean the piece of metal that *conducts electrons in and out* of the solution. [13]

H. The two half-cells [of a Daniell cell] are connected in two ways: by wire (or *electron conduit*) which allows [the] *flow of electrons* and by [...] The electrons released in the zinc block *flow through the wire* toward the copper block. [14]

I. Electrons are transferred [...] to the oxidizing agent after *passing through an external circuit* [...] The *electrons* [...] *travel through* the external circuit to the Cu(s) electrode, where they are consumed in the reduction of Cu^{2+} . [15]

Comments: In passage A, the first instance of ‘as’ (in “as through a tube”) might lead one to assume that the author is building a model, but the passage overall is declarative: “An electron [...] is pumped [...] The charge [...] is conducted by the motion of the ions.” And yet no valid statement of fact emerges, so we must consign the passage to the realm of *notions*. (My use of the term ‘notion’ is explained in the definition of ORTHODOXY above.) In B, the authors speak first of a battery causing “charge to move through a wire,” etc. So far so good. But later they lapse into the Orthodoxy whereby *electrons flow through the wire*. This creates a mixed message, teetering on the fence between science and fiction. In passage C, mixed in with the obligatory ‘electron flow’ patter we find two realistic-looking terms, ‘current’ and ‘charge passed.’ To us, this might suggest that the author’s *own* interests extend beyond the Orthodoxy to things more substantive, but that fleeting shift in the level of discourse is not much help to the naïve *student* using his textbook. (For perspective on the many instances of ‘electron flow’ in the electrochemistry literature as documented here and in Part Four below, consider the following ‘Pitfall Prevention’ from a freshman physics text [3]: “A battery does not provide electrons to the circuit. It establishes the electric field that exerts a force on electrons already in the wires.”)

Here I’ve assembled some specifics on electron drift and ion mobility, as context for the problem in the next paragraph: The drift velocity of an electron in copper is 1 meter per 75 minutes or

2.22×10^{-4} m/s [16; see also 17, 18]. Ions migrate at rates on the order of 6.8×10^{-4} cm/sec, 0.246 mm/min, or 2 cm/hr [19, 20, 21]. Expressed in m/s equivalents, that gives us: 6.8×10^{-6} , 4.1×10^{-6} , 5.5×10^{-6} . Let's note in passing that *current* makes indirect appearances in the literature as the numerator of the current density definition: $J = I/A$. But when expressed in terms of one-dimensional velocity, these rates too are found to belong, as usual, to the realm of electron drift, not electricity near c . Here are three such examples: "At a current density of 10^4 mA/cm², the rate of iron dissolution is about 0.15 mm/min" [22], m/s equivalent: 2.5×10^{-6} . "[For] iron at $j = 90$ Acm⁻², the rate of dissolution is 2 mm/min and for $j = 540$ Acm⁻² it is 12 mm/min" [21], m/s equivalents: 3.3×10^{-5} , 2.0×10^{-4} . Paraphrase: Pass 3 mA through cell with cross-sectional area of 3.25 cm² for 45 min; the boundary moves 2.13 cm. Rate: $2.13 \text{ cm}/45 \text{ min} \cong 7.8 \times 10^{-6}$ m/s [23].

To gain a better understanding of what these numbers mean in practical terms, let's now do a variation on a cell-charging problem. In paraphrase, the problem itself runs as follows: "If 10 A were passed through a lead storage cell for 1.5 hours, how much PbSO₄ would decompose? Answer: 170 g" [24]. Now, suppose we apply a representative drift velocity and migration rate to that procedure. It would take 352 million years for the 170 g to react, instead of 1.5 hours (as plausibly stated in the problem itself).

Assumptions/calculation: Let the electrode separation be 3 cm, as shown in Figure 1, where the circuit depicted is generic and may therefore be borrowed as an ad hoc adjunct to the PbSO₄ problem. The 3 cm separation accounts for 1% of the circuit's perimeter. For the 99% metallic regime, 99% of 1.5h is 1.485h; for the 1% electrolyte regime, 1% of 1.5h is 0.015h. Divide 3.0×10^8 m/s by 2.22×10^{-4} m/s (a representative electron drift velocity) and multiply the dimensionless result by 1.485h to obtain 2.00×10^{12} hours, or 228 million years. Divide 3.0×10^8 m/s by 4.1×10^{-6} m/s (a representative ion migration rate) and multiply by 0.015h to obtain 1.09×10^{12} hours, or 124 million years. Sum of years: 352 million years. (If applied to the procedure featured in Figure 1 itself, these same considerations require that the duration be revised from 1200 seconds to 78 million years.)

How can such a contradictions arise in elementary teaching materials? Short answer: The term 'electron flow' is the culprit; it should never have been coined so cavalierly on the physics side nor adopted so naively by electrochemistry. The makings of a longer answer are suggested in Tsaparlis: *In high school and college instruction, the quantitative/manipulative aspects of electrochemistry are*

emphasized, while qualitative understanding is neglected. When asked about their misconceptions, students attribute them chiefly to those traditional methods of teaching, which fail to reflect the complex and interwoven concepts of our field. [25, paraphrase]

Part Four: More Citations, now from specialized electrochemistry texts

In Part Three I documented the widespread use of the term ‘electron flow’ and label ‘ $e^- \rightarrow$ ’ in literature category (a). Here I conduct a survey of category (b), the specialized electrochemistry texts, to see if/how they move beyond the notion of ‘electron flow’ as presented to freshmen.

Except for “there *is* net transport” in passage J and “*or* ions” in M below, all italics in the quotations to follow are mine. As before, the italics flag manifestations of the Orthodoxy. Again, some terms hint at (or reflect clearly: passage N) a view that transcends the Orthodoxy, and I differentiate these terms by bolding.

J. The Quantitative Link between *Electron Flow* in the Electrodes and *Ion Flow* in the Electrolyte: **Faraday’s Law** [...] electron **current I_e** in the metallic part of the circuit must be equal to the ion **current I_i** [...] The bulk situation [for ions that are not in proximity to either electrode] is like the **random walk of electrons**; it can never yield *electron transport*. The interface situation is like the **drift, or flow**, of electrons; there *is* net transport and a **current** [...] There will be a *flow of electrons* in the metallic part of the circuit and an ionic flow in the electrolytic solution. [From context, it appears that Bockris & Reddy are speaking only of the *interface* vicinity, not the whole “metallic part.”] Follow the path of the **drifting charge** [...] If the external power source can keep *pumping electrons through the system* [...] [26]

K. [A] current source “pumps the electric fluid” [The] mobility of electrons [...] is responsible for electrical **conductivity** [E]lectricity as a “fluid” [...] naive model [...] ionic conductors [...] possess **conductivity** by virtue of the motion of anions and/or cations [E]lectronic conductivity [...] allows the *passage of electrons* [The] **electricity** is carried by the motion of hydrogen ions H^+ from right to left and by the motion of bisulfate ions HSO_4^- from left to right [...] Note that *electrons flow* through the load from right to left but, because electrons are negatively charged, we speak of **electricity**, or **electric current**, flowing from left to right through the load. [The current] flows clockwise as our cell is diagrammed. [27]

L. ...*supplying electrons* to the copper electrode with an external power supply [...] *electron flow* from a solution species *into the electrode* [...] Since i represents the number of electrons reacting with Cd^{2+} per second, or the number of **coulombs** of electric charge flowing per second, the question ‘What is i ?’ is essentially the same as ‘What is the rate of the reaction, $\text{Cd}^{2+} + 2e \rightarrow \text{Cd}$?’ [28]

M. Electric currents in electrolyte solutions *are* the directed motions of the ions under the influence of an applied electric field [i.e., ion migration] To sustain steady current flow, one needs a steady sink for the *particles arriving* and a steady source for *those departing* [...] At an anode, *electrons go away* from the junction into the metal [...] at a cathode, *electrons supplied by the circuit* must react [...] the interface [...] is crossed by species of one type: electrons [at the anode in the present example] *or* ions [at the cathode]. [29]

N. If the ions in an electrolyte solution are subjected to an **electric field** [the resultant force will] induce motion in or against the direction of the field [...] This *ion motion leads to the transport of charge* and hence to the flow of **electrical** [sic] **current** through the electrolyte solution [...] When current flows [...] ions migrate [The] fundamental difference between **charge transport** [...] **by** ion migration and [...] **by** electron migration. [30]

Comments: In passage J, if we only glance at the symbols I_e , and I_i it might seem that we have found an example of a specialized electrochemistry text compensating, at last, for the silence on (real) electric current at the freshman level. But look again. The meanings assigned to those symbols by the authors are ‘Electron Flow’ and ‘Ion Flow’, respectively; so this is the Orthodoxy dressed up to look technical. In II:848-854, the authors scramble terminology in ways that are embarrassing even in the context of the Orthodoxy. For example, they tell us the electron donations from ferric to ceric ions, adrift in the bulk solution, exhibit a ‘random walk,’ so there can be no ‘electron transport’ in the bulk solution. Not only is that way of alluding to the random walk of electrons wrongheaded and misleading (compare Figure 3), but having identified a mechanism that contributes *no* current to the ionic bulk solution they fail to offer an alternative mechanism that *does* account for completion of the circuit (viz., an electromagnetic wave aka electricity). Also, they have tacitly rechristened *charge transport* as “electron transport,” seen nowhere else in the literature. Next, by virtue of the word ‘or’ they equate *electron drift* (something real and measurable) with *electron flow* (something jargony and unreal). Finally, they juxtapose “flow of electrons” with

“drifting charge.” This simultaneously (a) denies the distinction between *electron drift* and *charge transport* and (b) confounds (nonexistent) electron flow with (real) electric current.

Oldham & Myland [27] start their book with a whole chapter on The Conduction of Electricity. It is heartening to see this feature, which is lacking in a number of other specialized electrochemistry texts. In passage K above, Oldham & Myland even employ the word ‘model’ which provides relief from the literalism of the Orthodoxy. And they say the mobility of electrons is *responsible for* electrical conductivity; similarly, ions are said to *provide* conductivity. All true statements. But the conclusion of Chapter 1 is disappointing. Ostensibly, this is where electric current itself will be defined in detail but in fact the discussion takes a detour (as I see it) into electron drift rates (without using that terminology). Never does the circle close on electricity itself. At the end of the chapter, attention turns instead to conventional current, signaled (implicitly) by the appearance of ‘ $e^- \leftarrow$ ’ versus ‘ $I \rightarrow$ ’. (Unaccountably, the term ‘conventional current’ itself is never mentioned.)

As for L, in another context the discussion of *i* and **coulombs** could make sense, but as presented it is tainted by language of the Orthodoxy that occurs two pages earlier.

Like the opening chapter in Oldham & Myland, the first chapter in Bagotsky (Electric Currents in Ionic Conductors) goes a long way toward remedying the silence on electricity that pervades the freshman-level literature. Yet though Bagotsky’s description of the cell in passage M is more precise and technical-*sounding* than what we see typically at the freshman level, it is in essence the same old Orthodoxy, dressed up a bit: At the anode, two $Cl^- (aq)$ ions supply a pair of electrons that flow counterclockwise through wires, necessitating the plating out of one Zn^{2+} at the cathode; such is Bagotsky’s scheme (paraphrased here). Contrast this with [4] where the notion of *any* M^+ plating out to M^0 is shown to be false. (Also, with “are” Bagotsky explicitly equates “electric currents” with “the directed [i.e., vectored] motions of ions.” This too harks back to the Orthodoxy and concomitant confusion about speed(s). Contrast this with N.)

In N, the authors (Hamann, Hamnett and Vielstich) provide a level of detail appropriate to a specialized text *and* their details are accurate. *Here at last we find an example that departs definitively from the Orthodoxy*, not just momentarily by veiled hints as noted in a few of the earlier examples. (I would have closed this series with a sixth passage labeled ‘O’ from Gileadi, except that he has been cited already in our definition of ELECTRICITY (Figure 3), and in Figure 2C. In [4],

Gileadi too offers a clear challenge to the Orthodoxy, although not in the comprehensive manner of passage N.)

Concluding Remarks

Already, everyone knows electrochemistry has *something* to do with electricity. Why, then, have I labored here to clarify and expand on that one small point? I did not do this work in a vacuum; it was motivated by an underlying philosophy of the macroscopic and atomic realms. Up here at the macroscopic level (where so much is illusory on the Vedānta viewpoint), there are precious few options available to us for ‘communing’ with entities down there at the atomic scale (where the only credible reality prevails, according to my bias). One way to bridge the gulf is through thought experiments based on the von Koch snowflake, an exercise that might be dubbed Twenty Degrees of Separation, by analogy with Six Degrees of Separation in the social sphere [34, 35].

Another way of communing with the atom is simply to *do chemistry*, with increased awareness of its bridge-building aspect, across the macroscopic/microscopic abyss. But for this to work one must have full confidence in the modeling of a given process. Early on, I could not help noticing that ‘electron flow’ is a factoid. My knee-jerk reaction to that disappointment was to review freshman physics, where surely I would find a wealth of material to fill in the blanks on the electrochemistry side. But as we have seen, it turns out that the electricity tradition in physics pedagogy possesses its own problems. Eventually, I felt there was no course open but to build my own model, by choosing selectively from physics texts then adding in Gileadi’s M^+ (in Figure 3).

Naïvely stated, one of the primary mottos related to my philosophy would be: Make Atoms Real (for the student). But this would not sit well with the Copenhagen interpretation of quantum theory, wherein atoms are not things, only tendencies [36]. Accordingly, one should revise the motto to read: Make the Atomic *Realm* Real. This does not mean, however, that we have agreed to a full retreat from Make Atoms Real. How so? Nick Herbert points out that a rainbow is *objective* (in one’s brain) even if it is not an *object* (in the sky) [37]. By the same token, a mercurial atom, even if it is just a bundle of tendencies, is still *objective* from a certain vantage point. (An objection might come from the opposite direction, as follows: “Neither the atom nor even its nucleons are now regarded as elemental; rather, quarks play that role.” In that case, my response would be to cite Douglas Hofstadter on chunking in general, and on the chunking of quarks in particular [38]. From

the chemistry viewpoint, never mind the commonsense viewpoint, the atom is the appropriate chunking level.)

A final thought on the term ‘electron flow’ as presently used in electrochemistry pedagogy: Not only does it break the science compact (because it is a fairy-tale), but it does double harm by simultaneously robbing the student of the opportunity to contemplate something truly wondrous: namely, charge transport near c , a phenomenon that, in its way, is just as remarkable as the one Einstein found so mesmerizing as a child of four or five: the movement of a compass needle [32]. Given its ubiquity, one cannot imagine the term ‘electron flow’ being abandoned, ever. By definition, factoids are forever. But at least future authors might try to recast the term as part of an explicit simplifying *model* (albeit a poor model, grandfathered in) rather than allowing it to persist as the centerpiece of a silently entrenched *myth*.
